### Abstract

The buildings of the NUHZ (New Urban Housing Zone) in Algeria have an alarming energy situation, considering that poor thermal design leads to energy overconsumption. This research has highlighted the factors affecting thermal comfort in this type of housing. In this regard, the solutions for the requalification and energy renovation of NUHZ building housing have become immediate and urgent in order to reduce energy consumption and achieve high-energy performance buildings. Therefore, improving the existing framework is essential to restore quality to this housing stock and ensure its energy performance. The requalification of the buildings stands out as a key operation in the overall response to this issue. The main objective is to reduce energy consumption in existing social housing while ensuring its thermal comfort. Our research enabled us to conduct an analytical and comparative study between the energy balance of social housing before and after its energy requalification.

Keywords: high-energy performance, energy requalification, thermal comfort, the NUHZ.

### Introduction

Energy is a crucial factor for the survival of societies and essential for meeting daily needs as well as for economic and social development. However, this energy primarily relies on non-renewable fossil fuels (gas, oil, and coal), which are expected to deplete in the medium term [1]. In 1973, the first global oil crisis marked the beginning of a global energy and environmental crisis for the building sector and the introduction of the first thermal regulation in France: the RT 1974[2]. Global energy consumption increased by 42% between 1990 and 2008, from 354 quadrillion Btu (British Thermal Units) to 505 quadrillion Btu. This consumption is projected to increase by 53% between 2008 and 2035, from 505 quadrillion Btu in 2035.

A significant portion of the growth in energy consumption occurs in non-OECD countries (Organization for Economic Cooperation and Development), driven by economic growth.

Energy use in non-OECD countries is expected to increase by 85%, compared to an 18% increase in OECD economies [3].

BP's "New Momentum" scenario envisions a rise in global final energy consumption until around 2040, before stabilizing (with global demand in 2050 expected to be 10% higher than the 2019 level) (Fig 01). In its two other "accelerated transition" scenarios, BP estimates that global final energy consumption in 2050 should be 15 to 30% lower than the 2019 level, thanks to rapid progress in energy efficiency. It is important to note that all three of BP's scenarios anticipate a roughly 75% increase in global electricity consumption by 2050.

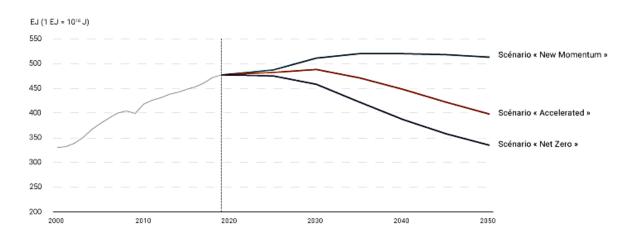

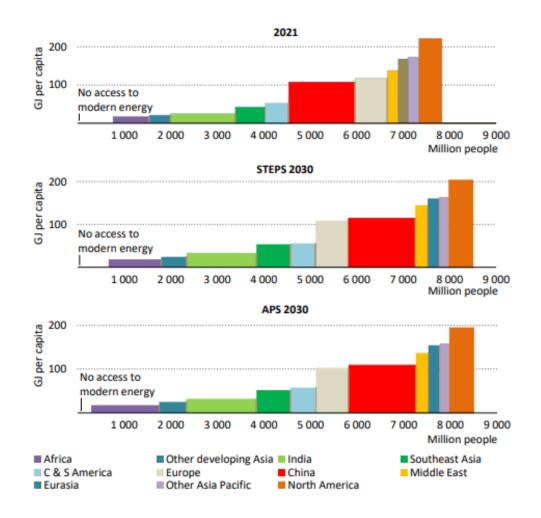

Figure 1- évolution de la consommation finale d'énergie dans les différents scénarios du BP Energy Outlook 2023. (BP Energie Outlook. (2023))

*Figure 2.Total moderne energie supply per caapita by region in the STEPS and APS, 2021and 2030. (BP Energie Outlook. (2023))* 

In recent years, per capita energy demand has been on the rise. This is why the exploration of approaches that promote the development of thermal regulations (including RT2012) and environmental regulations (RE2020) is necessary to support ecological and energy transition. The High Energy Performance (HPE) and the 1983 solar label serve to enhance the performance requirements of future thermal regulations: ... In 2008, the requalification towards high performance. This is why numerous laws have been enacted, plans have been implemented, and commitments have been made to reduce energy consumption in the housing sector [4].

Certainly, in recent years, the proliferation of experimental building performance certification protocols has led to the strengthening of requirements for thermal and environmental regulations. Paradoxically, the proliferation of normative guarantees often appears as an obstacle to ecological solutions in architecture [2].

For instance, the European Union committed to the 2020 energy-climate package in 2008, which consists of a set of directives aiming for a 20% reduction in greenhouse gas emissions

compared to 1990 levels, achieving 20% renewable energy in final consumption, and increasing energy efficiency by 20%, particularly in the building sector. In 2014, new targets were set for 2030, notably pushing for a 40% reduction in GHGs compared to 1990 (Climate Challenge of Cities, 2018). This framework was further revised in 2018 to include 32% renewables as opposed to 27%, and at least 32.5% energy efficiency actions compared to 27%. Thus, "European states are required to adopt integrated national energy and climate plans (NECPs) for the period 2021-2030 and to develop long-term national strategies, ensuring coherence between their long-term strategies and the NECPs."

Energy-related issues are becoming increasingly important in both society and public policies, both at national and local levels. Housing, being a highly energy-consuming sector, places energy-related questions at the forefront [5]. The global issue of the sustainability of fossil fuels underlies the development of energy efficiency policies on an international scale.

## **Related works**

Algeria, being one of the producers and exporters of fossil fuels, is no exception. In 1990, the country launched a national program aimed at energy management, which encompassed various sectors, notably the residential sector. This sector, considered today as the most energy-intensive, saw the initiation of a program involving 600 high energy performance (HPE) housing units. The project's objective is twofold: firstly, to reduce household energy consumption, and secondly, to ensure a 40% thermal comfort for these residences, in accordance with local requirements [6].

Legislatively and regulatory-wise, Algeria has a significant legal framework for rationalizing energy use, though these measures remain largely unenforced on-site due to a lack of oversight in this domain:

- Law No. 99-09 of July 28, 1999, relating to energy management.
- Executive Decree No. 2000-90 of April 24, 2000: It establishes thermal regulations for new residential buildings.
- Law 04-09 of August 14, 2004, regarding the promotion of renewable energies in the context of sustainable development.
- Executive Decree 04-149 of May 19, 2004, outlining the modalities for developing the national energy management program.
- Executive Decree No. 05-16 of January 11, 2005, setting specific energy efficiency rules for devices operating on electricity, gas, and petroleum products.

• Interministerial Order of November 29, 2008, defining the energy efficiency classification of household appliances.

The National Agency for the Promotion and Rationalization of Energy Use also oversees energy management and covers all measures and actions implemented in terms of rational energy use and renewable energy development. It addresses the concerns of the Ministry of Energy and Mines through the following instruments [7]:

- 1. The Sectoral Committee for Energy Management (CIME in French)
- 2. The National Fund for Energy Management (FNME in French )
- 3. The National Energy Management Program (PNME in French): This includes
  - The framework and perspectives of energy management.
  - The evaluation of potentials and definition of energy management objectives.
  - The existing and to-be-implemented means of action to achieve long-term objectives.
  - A five-year action program.

This latter program includes the following:

- 1. Top-Industry Program
- 2. Prop-Air Program
- 3. Eco-Light Program
- 4. Alsol Program
- 5. Eco-Build Program

The objective is to carry out a demonstrative action that proves the feasibility of introducing energy efficiency in Algeria, contribute to the widespread adoption of best practices in architectural design for housing, and ultimately promote compliance with regulatory standards. Unlike the complementary role of most previous programs, the Eco-Build program appears significant because it focuses on designing energy-efficient buildings. Thus, the residential sector emerges as a top priority for energy management due to its high consumption levels.

In Algeria, the thermal regulation is governed by Executive Decree No. 2000-90, which is included in Law No. 99-90 relating to energy management in the building sector. This regulation aims to introduce energy efficiency in new residential and other buildings. Its implementation is expected to achieve more than 40% energy savings for heating and air conditioning needs. Through this regulation, the National Center for Studies and Research in

the Building Industry (CNERIB in French) has prepared three technical regulatory documents for building professionals:

- DTR.C 3-2, which establishes rules for calculating winter heat losses for residential buildings.
- DTR.C 3-4, which deals with rules for calculating summer heat gains for buildings.
- DTR.C 3-31, which addresses natural ventilation for residential premises.

This regulation enhances the overall energy performance of buildings, providing ample opportunities for designers and developers to choose between overall thermal performance of the building, including the choice of materials and building framework design. The Algerian regulation draws significant inspiration from French regulations, particularly in the aspect of thermal insulation. The concern, however, lies in the fact that there are regulations for new constructions, but not for existing ones. A large portion of the Algerian population has been living in HLM (public housing) and multi-apartment buildings since independence, as the primary concern at that time was to provide housing for as many Algerians as possible, with standardized plans for both the north and the south, neglecting considerations for thermal comfort.

Labels serve as indicators of comfort, energy performance, and environmental compliance, aiming to create buildings with low energy consumption. They rely on reference frameworks and are subject to audit and evaluation procedures. The main labels, particularly European ones, include PASSIVHAUSS (Germany), MINERGIE® (Switzerland), MINERGIE® standard, MINERGIE-P® (passive), MINERGIE-Eco (ecological), MINERGIE P-Eco (passive and ecological), and ZERO ENERGY BUILDING (USA). French labels include EFFINERGIE, which corresponds to the Low Consumption Building label. Additionally:

- HPE 2005 (High Energy Performance): Associated with the 2005 thermal regulation, but more demanding. This label has two performance levels.
- THPE 2005 (Very High Energy Performance): Concerns buildings with at least 20% lower conventional energy consumption than the reference consumption in the 2005 thermal regulation.
- HPE EnR 2005 (High Energy Performance Renewable Energies 2005): In addition to meeting HPE requirements, this label requires the use of renewable energies, with at

least 50% of the energy used for heating coming from a biomass installation or a district heating network using over 60% renewable energies.

- THPE EnR 2005 (Very High Energy Performance Renewable Energies): Pertains to buildings with at least 30% lower conventional energy consumption than the reference consumption in the 2005 thermal regulation. These constructions must also use renewable energies such as biomass, solar thermal or photovoltaic, and highly efficient heat pumps.
- BBC 2005 (Low Consumption Building) or EFFINERGIE: Requires that the energy consumption of residential buildings be at most 50 kWh/m<sup>2</sup>.year depending on the climatic zone and altitude. For non-residential buildings, the conventional energy consumption must be at least 50% lower than the reference consumption according to the 2005 thermal regulation.

In summary, energy labels can be classified based on their energy consumption requirements into three categories: **efficient** (Minergie, Minergie-Eco), **very efficient** (Minergie-P, Passivhaus, and Effinergie), and **zero energy or positive energy**. Labels for energy performance generally operate on the same principle, namely, reducing energy needs and supplementing them with efficient systems using various energy sources, including renewables.

Heating needs are reduced through improved thermal insulation, the reduction of thermal bridges, and good air tightness. Summer comfort is addressed through passive solutions, sometimes combined with efficient cooling systems. Comprehensive labels and global approaches consider the interaction of the building with its environment from a broader perspective, where energy efficiency is just one aspect of these interactions. Examples include LEED (Leadership in Energy and Environmental Design) in the USA, CASBEE (Comprehensive Assessment System for Building Environmental Efficiency) in Japan, BREEAM (Building Research Establishment Environmental Assessment Method) in Great Britain, and HQE (High Environmental Quality) in France. These methods assess the environmental impact of different types of buildings (office buildings, residential buildings, commercial spaces, and industrial buildings). They integrate energy performance as an environmental requirement to be met, without setting specific performance targets.

These building concepts are defined by a set of objectives (desired performance level) and technical solutions intended to guide the designer. The designer, using various design aids,

combines techniques, materials, structures, and equipment to best achieve the set objectives. High-energy performance is a recent concept that has already been integrated into French regulations. It refers to the reduction of energy consumption through appropriate architectural design to enhance thermal comfort. Energy performance is defined according to the "total cost," energy balance, and maintenance and renewal cycles. The definition of an energetically efficient building is a comprehensive concept that encompasses architecture, climate, building envelope, and equipment.

The energy management of existing buildings starts with understanding the construction and its consumption patterns, with the organization of various relevant services and human resources. This involves gathering administrative data regarding the building's situation (contracts, invoices, floor area, types of activities, etc.) and technical data including plans, technical diagnostics, and energy and fluid consumption. Next, a strategy and action plan with medium- and long-term objectives must be defined, taking into account the state of the assets and available resources. Finally, monitoring the implemented actions is necessary to ensure planned objectives are met.

In the spirit of requalification, several experiences have been undertaken worldwide, although not in Algeria. Examples include the requalification of a 106-unit social housing building 'Moulin Lambert,' the renovation of 176 housing units... through thermal regulations and various other initiatives. Additionally, buildings constructed within the framework of the requalification of the former RN305, designed according to thermal regulations with a 20% reduction, ultimately achieved HPE level. The Grenelle project, which aims to reduce energy consumption and greenhouse gas emissions from buildings, is a top priority of the Environmental Grenelle. Its implementation in the existing housing stock is particularly important given the size of the stock: 32 million housing units, including nearly 8.5 million in co-ownership and 17 million individual houses. The objective of the Environmental Grenelle is to reduce energy consumption in the existing building stock by at least 38% by 2020. The multi-year investment program (PPI) has defined the need to undertake major renovations of 400,000 housing units, per year between 2013 and 2020, and by 2020, intermediate renovations for 9 million housing units.

As part of the National Energy Management Program (PNME), Algeria has launched a project to develop high energy performance housing nationwide. The Eco-Bat program involves the construction of 600 high energy performance housing units, covering various

climate zones in the country. This program aims to introduce energy efficiency in buildings and aims to achieve a 40% energy savings for heating and cooling.

Economic profitability is another concept used in the building sector to measure its performance. It represents the ratio between the initial investment of a construction and the gains that can be generated in the long term. The profitability of energy management actions is not exclusively economic. It involves several other aspects: energy, thermal comfort, well-being, and more

# **Case study :**

Annaba, a city in northeastern Algeria (figure 3), is considered one of the highest energyconsuming cities due to the presence of a significant residential housing stock, particularly the New Urban Housing Zones (NUHZ) which play a significant role. The residential sector accounts for 35% of final energy consumption in Algeria. The prospects for expanding the housing stock will lead to an exponential increase in this energy consumption. In this context, the design and construction of energetically efficient housing become a necessity for controlling energy consumption in this sector [19].

Figure 3 Location of ANNABA city. (source; Estockphoto.2023)

The chosen site is the New Urban Housing Zone (NUHZ) in the western plain for the following reasons:

- The western plain NUHZ is the first NUHZ implemented in the city of Annaba.
- According to the urban planning department, a large number of NUHZs are located in the western plain. The western plain I has 3,209 housing units, and the western plain II

# has 3,350 housing units (table 1). Energy consumption in sector 3 is higher compared to other sectors (table 2).

Table 1 Operations of the New Urban Housing Zones (ZHUN) in the western plain of the city of Annaba (1976-1987). (Source : Rouaibia, 2012).

| Opérations   | Superficy | Théorical Capacity | Density   | Housing completed |
|--------------|-----------|--------------------|-----------|-------------------|
|              | ha        | (house)            | houses/ha |                   |
| West-plain I | 110       | 3688               | 33,52     | 3209              |
| Est plain II | 194       | 5200               | 26,80     | 3350              |

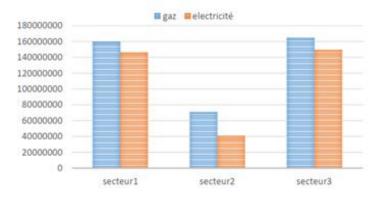

Figure 4 Gas and electricity consumption in the 3 sectors of the city of Annaba. (Source Sonalgaz2020)

The land is circled on the following map (figure 4) and which belongs to the NUHZ II district which is located in the northwest part of the West Plain district.

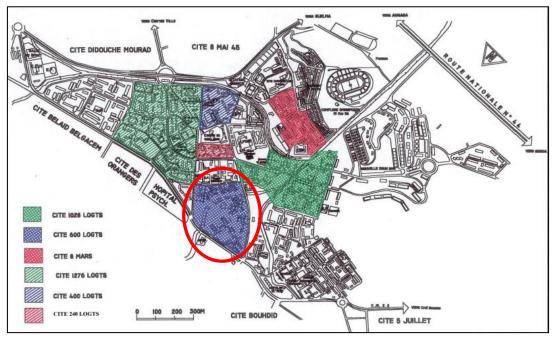

Figure 5 the NUHZ II district

The land belongs to the NUHZ II district, which is located in the northwestern part of the western plain district. The building (figure 6-7) is situated in the southwestern end of the district (figure 5- 6).

- District: 600 housing units
- Total Land Area (ha): 10.57
- Net Land Area (%) : 9.53
- Net Density (housing units/ha): 62.95
- Net Floor Area Ratio (CES): 0.22

# **Results and discussion :**

#### **Climatic analysis :**

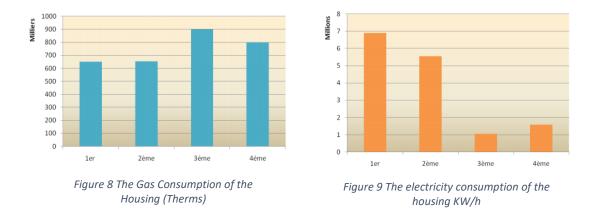

The climate in Annaba is mild, rainy in winter, and hot and subhumid in summer with an average maximum temperature of 32°C in August and an average minimum of 6.58°C in January. Humidity levels are high both in winter and summer, with a maximum average of 93% in December and a minimum average of 46.4% in July. Sunshine is considerable in summer with a maximum of 356 hours in July and a minimum of 98.9 hours in December. Precipitation is rare in summer and significant in winter, with a maximum of 136.16 mm in December and a minimum of 4.22 mm in July.

Annaba enjoys a Mediterranean climate. It is known for its long, hot, and dry summers. Winters are mild and humid, with rare snowy days. Rainfall can be abundant and even torrential. It is generally hot, especially from mid-July to mid-August.

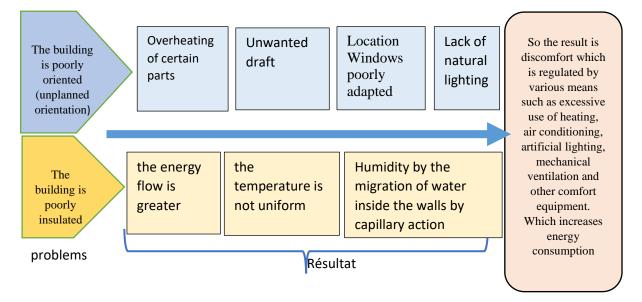

The layout of the site plan creates a courtyard where the spacing between buildings is small. This affects the sunlight exposure (L = 8m), limiting the penetration of solar rays for lower floors (L =  $(2.7n-a)/\tan h$  with H: sun height; n: number of levels; A: height of the sill; L: width).

- Maximum exposure on southwest-facing facades, while northeast-facing facades have no solar protection, whether natural like trees or artificial like sunshades, causing overheating of rooms due to intense summer heat.
- The arrangement of the buildings in a U shape causes gusts within the courtyards, and the absence of vegetation barriers increases the speed of cold winds.
- Cross-ventilation of the building and the absence of protections against cold winds allow the penetration of winter drafts, creating uncomfortable internal air currents.
- Walls: Prefabricated elements in reinforced concrete of sandwich type with insufficient insulation made of (polystyrene and cork)  $\lambda$ =1.75. Very low performance.
- Glazing: Wooden window openings with Ug = 0.23 W/m2. Single glazing: clear 3mm glass installed with putty. Very poor performance = 4.15.
- Insulation materials (polystyrene and cork) are used in facade panels and for the 3cm thick roof (insufficient to guarantee comfort in winter and summer).
- The study unit is equipped with auxiliary heating with a capacity of 1900 to 11,000 Kcal/h, located in the entrance hall, which proves to be insufficient in thermal terms on

the coldest days of the year. The cooling device is a window air conditioner with an efficiency of:

The increase in electricity consumption occurs in the 3rd quarter of the year (figure 8-9), due to the use of air conditioners in the summer season. As for gas consumption, the most significant increase occurs in the 1st quarter of the year, which encompasses the coldest months.

*Figure 10 problems linked to insulation and poor orientation of the case study building.* 

#### **Result of Mahoney Tables Analysis**

Through the application of the Mahoney method (table2), we arrive at a number of recommendations necessary for achieving hygrothermal comfort in a building designed for the city of Annaba. Following this analysis, the following recommendations are outlined; (section 1-2-3-4):

| Localisation  |          |      |       |       |       |       | ANN       | ABA  |    |     |      | D     | onn  | ées cl | limatiq      | ues        |

# Site Plan and Solar Mask Study

The arrangement of the buildings in a U-shape leads to gusts in the inner courtyards, and the absence of vegetation barriers increases the speed of cold winds.

Table 4 Sunlight exposure

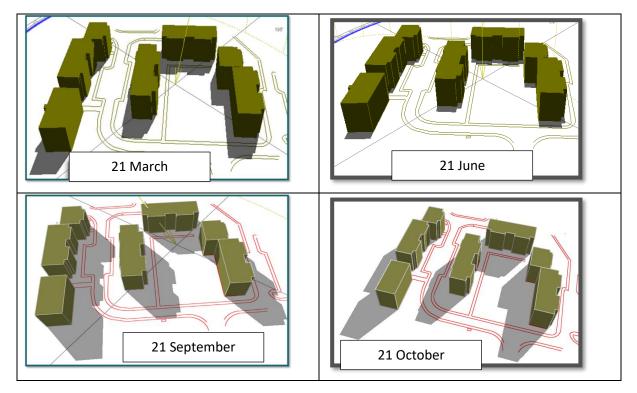

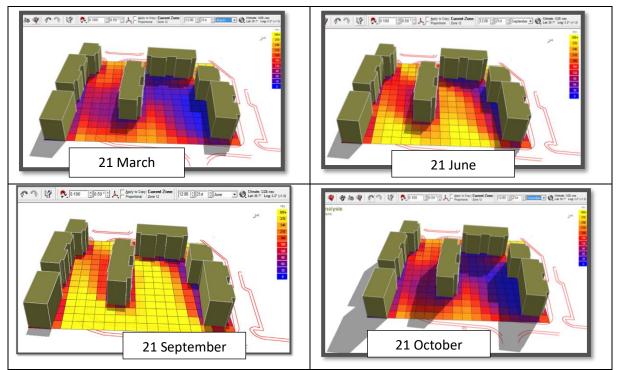

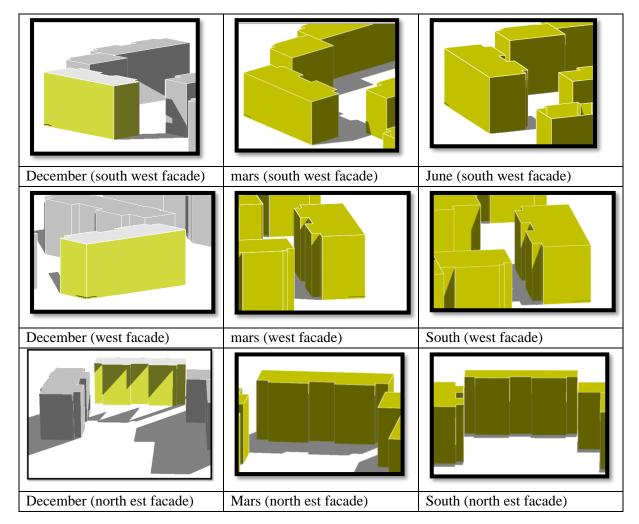

Table 5 solar radiation

The central part is less exposed to the sun and almost entirely shaded, receiving over 900 hours of sunlight (table 5).

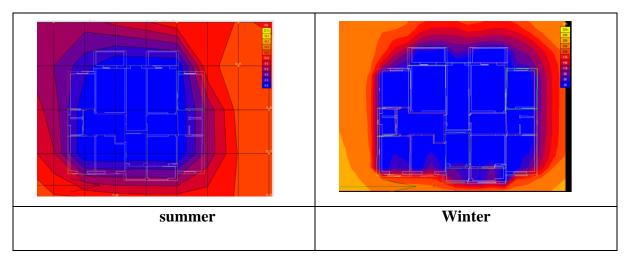

Table 6 solar exposure on facades

Sunlight exposure is low on the northeast facade, with some areas receiving less than 1 hour of sunlight per day regardless of the time of year (table 4-5). Natural light is very limited on the main northeast facade. The facade (table 6) is coated with an off-white or beige paint. To combat heat, reflective paints, typically in white, are used. Designed for outdoor applications, they ideally reflect a large portion of solar radiation, reducing the heating of buildings exposed to the sun. Solar radiation inside buildings (table 7) is desirable in winter but remains undesirable in summer.

There is little sunshine on the North-East Facade where certain parts receive less than 1 hour of sunshine per day whatever the time of year, the availability of natural light is very limited in the main north-east façade.

#### Table 7 Solar radiation inside buildings in summer and winter

The sunlight is insufficient in the unit due to:

• The inadequate orientation of the building (Northeast).

• The size of the openings, which affects both thermal and visual comfort in winter.

Solar radiation inside buildings is desirable in winter, but remains undesirable in summer

The solar rays are insufficient in the cell because of:

Inadequate building orientation (North-East).

The size of the openings, which influences thermal and visual comfort in winter.

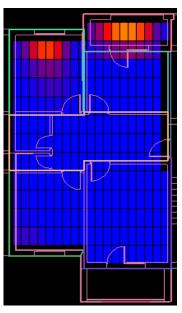

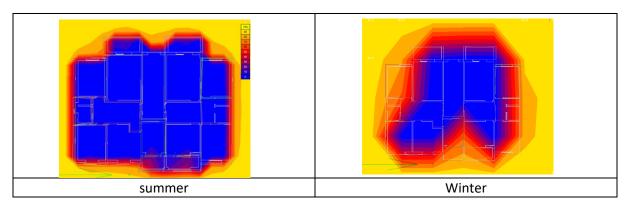

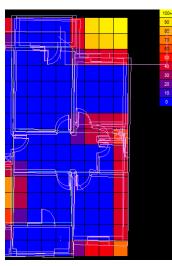

Figure 11 Solar radiation inside buildings

#### The lighting of the rooms:

The dwelling is characterized by insufficient light intensity during winter, where the penetration of solar radiation is limited for the north-facing rooms (bedroom) (figure in table 8).

Table 8 the lighting of the rooms

The house is characterized by insufficient light intensity during winter where the penetration of solar radiation is limited for north-facing rooms (bedroom) (figure 13).

#### Ventilation Losses Qv

The orientation of the building towards the prevailing wind, along with the absence of protection against cold winds, leads to the penetration of winter breezes and the creation of inconvenient internal drafts. The use of materials with low thermal performance:

Figure 12 light intensity during winter

The walls are of a prefabricated tunnel system made of concrete with a performance value of  $\lambda$ =1.75, and the windows have poor performance with a value of 4.15. This results in a shorter thermal lag

time, leading to overheating of internal spaces and poor thermal insulation.

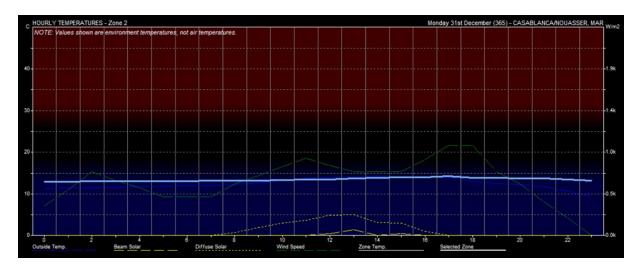

Figure 13 Ventilation Losses Qv of internal spaces.

#### Recommendations

- On the scale of the envelope
  - Reinforce the insulation of the roof (green roof)
  - Work the angles to reduce the mask effect
  - Favor light colors for shaded facades
  - Installation of vegetation in the heart of the island to reduce the effect of gusts
- At the cell level
  - Add protection on the exposed side (southwest)
  - Reinforce exterior insulation
  - Rearrange spaces (day space towards the south)
  - Rework the balconies

the active and passive actions undertaken on the house in the case study to improve its performance (table 9).

Table 9 active and passive actions

# Conclusion

In terms of well-being, HPE housing has also proven to be profitable. The requalification of buildings has ensured thermal comfort. The evaluation of the overall cost of high-energy performance construction compared to its initial state (in our case, Public Rental Housing) has demonstrated that all benefits in the short, medium, and long term result from the good spatial configuration and orientation of the housing. Architectural solutions for sun protection, technical insulation details, and all means directly or indirectly ensure thermal comfort in the housing. Ensuring the thermal comfort of existing housing requires thoughtful energy requalification through renovation or well-considered rehabilitation.

Our research has shown that through this type of requalification, gains can be made in both energy and economic aspects. This experience will have positive impacts on the environment and climate change through the reduction of energy consumption.

Efficiency is achieved through the application of passive and active improvement solutions at the level of the envelope and internal space, as well as by strengthening the envelope through wall and floor insulation, double glazing, and the use of green roofs, which contribute to reducing thermal losses in combination with natural ventilation. Applying high-energy performance standards to existing buildings to minimize energy consumption in the residential sector is a necessity.

Passive measures involve architectural and construction interventions. This includes working on volumes, the orientation of the building, the placement of openings that determine natural lighting and ventilation, thermal insulation, etc. Active measures include, for example, local or central heating, mechanical ventilation and cooling, artificial lighting, etc., which aim to compensate for building deficiencies or complement passive measures.
